Abstract

The fluorometric Amplex UltraRed AmR assay is frequently used for quantitative assessment of hydrogen peroxide production. It is specific to H₂O₂, can be calibrated accurately, and allows continuous real-time measurement. Without correction for the background fluorescence slope, however, H₂O₂-independent formation of the fluorescent product UltroxRed (or resorufin) leads to artefacts.

We analysed (1) the medium specificity of the background fluorescence slope of the AmR assay, and (2) the oxygen dependence of H₂O₂ flux in baker's yeast *Saccharomyces cerevisiae*. Apparent H₂O₂ flux, O₂ concentration and O₂ flux were measured simultaneously by high-resolution respirometry equipped with the fluorescence module. The apparent H₂O₂ flux of yeast showed a maximum under hypoxia when incubated in Dulbecco's Phosphate Buffered Saline DPBS or KCl-medium. This hypoxic peak increased with the sequential number of normoxic-anoxic transitions. Even in the absence of yeast, the fluorescence slope increased at low O₂ levels as a function of fluorescence intensity. The hypoxic peak was not observed in mitochondrial respiration medium MiR05.

Author contributions

EG and OS designed the work; OS and TK collected data; OS and TK analyzed data; TK, OS, and EG wrote and revised the article.

Conflicts of interest

EG is founder and CEO of Oroboros Instruments, Innsbruck, Austria.

Therefore, the hypoxic peak was a medium-specific background effect unrelated to cell physiology. In MiR05, H₂O₂ production of yeast decreased linearly from hyperoxia to hypoxia, with a steep decline towards anoxia. Respiration and oxygen dependence expressed as p_{50} of yeast were higher in MiR05 than DPBS. Respiration was a hyperbolic function of oxygen concentration in the low-oxygen range. The flux-dependence of oxygen affinity explained the higher p_{50} in MiR05.

1. Introduction

The formation of reactive oxygen species ROS is an inevitable side effect of aerobic respiration (Skulachev 1996). ROS involve several chemical species of reactive molecules derived from oxygen in redox reactions including photo- and chemiexcitation (Sies and Jones 2020). Physiologically, ROS play a vital role in many redox signaling processes such as differentiation and apoptosis (Brand 2016; Buettner et al 2013). The imbalance between generation and removal of ROS via the antioxidant systems leads to *oxidative stress*, which is accompanied by damage of proteins, lipids and nucleotides, disturbance of cell metabolism, and derangement of ROS signaling (Paniker 1970; Sies 1997; Xiao, Loscalzo 2020). According to the concept of *reductive stress*, reduced compounds – e.g. NAD(P)H and glutathione – accumulate at low oxygen levels causing high ROS production under hypoxia, inducing hypoxic oxidative stress and disturbing redox homeostasis (Aon 2010; Dawson et al 1993; Korge et al 2015; Xiao, Loscalzo 2020).

Quantification of ROS species is challenging due to their short lifetime, ranging from nanoseconds to seconds. An ideal probe for ROS measurement (1) reacts rapidly with ROS to outcompete the cellular antioxidant systems, (2) produces a stable, measurable, and quantifiable product, (3) is specific to a particular ROS species, and (4) has sufficiently high sensitivity (Dikalov, Harrison 2014). Measurement of changes in fluorescence caused by oxidation of molecular probes provides a convenient way for determination of ROS production. Most popular assays for determination of ROS production are based on Amplex UltraRed™ (AmR), dihydroethidine (DHE), and 2',7'-dichlorofluorescein diacetate (DCFH-DA).

The AmR assay is one of the most frequently applied methods for assessing H₂O₂ production. H₂O₂ is the most stable form of ROS. AmR reacts with H₂O₂ catalyzed by horseradish peroxidase HRP, forming the fluorescent product resorufin Res in the case of Amplex Red or Amplex UltroRed (xRed) in the case of Amplex UltraRed. Superoxide dismutase SOD converts superoxide to H₂O₂ which can freely cross biological membranes (Bienert et al 2006). According to Mohanty et al (1997) AmR does not cross biological membranes, whereas other studies show the contrary (Miwa et al 2015). Benefits of this method are (1) the high sensitivity towards H₂O₂ (Mishin et al 2010; Tretter, Ambrus 2014) compared to DCFH-DA (Dikalov, Harrison 2014; Kalyanaraman et al 2012; Mohanty et al 1997), (2) the simple and accurate calibration of the fluorescence signal using H₂O₂, since the fluorescence signal (i.e. fluorescence intensity) is a linear function

of added H₂O₂ concentrations up to 5 μM (Tretter, Ambrus 2014) or up to 3 μM resorufin (Krumschnabel et al 2015), (3) the low inhibitory effect on mitochondrial (mt) respiration compared to other fluorescence dyes used in studies of bioenergetics, e.g. safranin (Makrečka-Kuka et al 2015), and (4) instantaneous consumption of H₂O₂ (less than 5-10 s; Tretter, Ambrus 2014) which makes this probe an ideal candidate for real-time and continuous measurement of H₂O₂ production. Disadvantages of the AmR assay are that the fluorescent product Res or xRed may be formed by H₂O₂-independent side reactions. These side reactions can be measured as the increase over time (slope) of background fluorescence intensity in the absence of sample without addition of H₂O₂: (1) in the absence of HRP during photooxidation of AmR upon light exposure (Zhao et al 2012), and (2) in the presence of HRP as spontaneous autooxidation of AmR (Zhou et al 1997). The components of the respiration medium exert an effect on the background fluorescence slope and thus influence the H₂O₂-sensitivity of the AmR assay (Krumschnabel et al 2015; Komlódi et al 2018).

In the present study, we investigated in various respiration media (1) the background fluorescence slope of the AmR assay at different O₂ concentrations, and (2) the O₂ dependence of the apparent H₂O₂ flux in yeast cells as a model system.

2. Materials and methods

2.1. Reagents

All chemicals were purchased from Sigma Aldrich (Carlsbad, CA, US) with exception of diethylenetriamine-N,N,N',N'',N'''-pentaacetic acid DTPA (Dr. Ehrenstorfer GmbH; Augsburg, Germany), Amplex UltraRed™ and Dulbecco's Phosphate-Buffered Saline DPBS (Thermo Fisher Scientific, Waltham, MA, US). MiR05-Kit (Oroboros Instruments, Innsbruck, Austria), DPBS and KCl-based respiration medium were used for simultaneous high-resolution respirometry HRR and fluorescence measurements. Components of respiration media are listed in [Table 1](#).

2.2. Yeast preparation

Commercially available freeze-dried baker's yeast (*Saccharomyces cerevisiae*) was rehydrated in Na-phosphate buffer (50 mM Na₃PO₄; pH 7.1) at a concentration 20 mg/mL at 30 °C to 40 °C preserving high viability (Crowe et al 1998; Koga et al 1966). The yeast suspension was pipetted 20-times slowly and 10-times fast up and down in a 2-mL Eppendorf tube using a 1-mL pipette since the cells sediment and clump rapidly. Immediately afterwards, 20 μL yeast suspension was injected using a 50-μL Hamilton syringe into the O₂k-chamber through the titration capillary of the stopper. The experimental concentration of yeast was 0.2 mg/mL unless otherwise indicated.

2.3. High-resolution respirometry

O₂ concentration and xRed fluorescence were measured simultaneously using the O₂k-FluoRespirometer (Oroboros Instruments, Innsbruck, Austria). The Oroboros O₂k continuously monitors the O₂ concentration and plots in real-time the O₂ consumption of

the biological sample. The O2k consists of two instrumental chambers which are designed to perform unlimited titrations during the experimental assay. All experiments were performed under constant stirring (750 rpm) in pre-calibrated 2-mL chambers. Polarographic oxygen sensor POS tests including air calibration (every experimental day) and monthly instrumental O₂ background tests including zero calibration of the POS were performed routinely as instrumental quality control (Doerrier et al 2018; Gnaiger 2001; 2008). The oxygen solubility of the medium at 37 °C was 9.72 μM/kPa for conversion of partial pressure to O₂ concentration equivalent to the O₂ solubility factor of 0.92. The volume-specific oxygen flux J_{V,O_2} was calculated as the negative time derivative of the O₂ concentration by DatLab 7.4. The O₂ flux was corrected for instrumental O₂ background flux $J^{°}O_2$.

Sequential anoxia-reoxygenation cycles were performed to measure ROUTINE respiration in DPBS, KCl-medium or MiR05 without addition of external fuel substrates. Reoxygenations were performed by opening the chamber to the stopper-spacer position to obtain a well-defined gas phase above the aqueous phase ('open' chamber). To decrease the O₂ concentration, nitrogen gas was injected with a 60-mL syringe into the gas phase obtained in the open chamber. The chambers were closed when approaching the required O₂ level.

Table 1. Composition of respiration media with concentrations [mM]. DPBS: Dulbecco's Phosphate-Buffered Saline; MiR05 (Gnaiger et al 2000); KCl-medium (Hoffman et al 2007).

BSA [mg/mL]	1	-	0.5
pH	7.1 (KOH; 30 °C)	7.0-7.3 (KOH, HCl; 24 °C)	7.4 (KOH, HCl; 24 °C)

2.4. Oxygen kinetics

Oxygen kinetics is assessed in a closed chamber during normoxic-anoxic transitions when the O₂ concentration decreases to zero (Gnaiger et al 1995; Gnaiger 2001). The oxygen concentration at which O₂ flux is reduced to 50 % is the kinetic parameter c_{50} [μM] or p_{50} [kPa] calculated from the hyperbolic fit comparable to Michaelis-Menten kinetics. The maximum enzyme reaction velocity V_{max} at saturating substrate concentration corresponds to pathway flux J_{max} in mitochondria or cells. Oxygen kinetics was measured

in freeze-dried baker's yeast in DPBS and MiR05 at 37 °C in the ROUTINE state without exogenous substrates. Importantly, J_{V,O_2} was corrected for instrumental O_2 background. Zero oxygen calibrations were obtained after normoxic-anoxic transitions. The first-order exponential time constant τ of the POS was determined by stirrer tests at $\tau = 2.9$ s for signal deconvolution (Gnaiger 2001). The data recording interval of 2 s was sufficient for resolution of O_2 kinetics at low O_2 affinity of yeast cells. Calculations were performed automatically by an O_2 kinetics software (Python; Doerrier et al 2018).

2.5. Hydrogen peroxide flux

Fluorescence was measured using Smart Fluo-Sensors Green (Oroboros Instruments; excitation 525 nm, emission ~600 nm). Sensors were inserted through the front window of the O2k-chambers. Horseradish peroxidase HRP (1 U/mL) and superoxide dismutase SOD (5 U/mL) were titrated into the chamber before Amplex UltraRed® AmR (10 μ M). The iron chelator DTPA (15 μ M) was applied to decrease the background fluorescence slope of the AmR assay (Kömlödi et al 2018). DPBS(+), KCl-medium(+), and MiR05(+) contained DTPA; DPBS(-), KCl-medium(-), and MiR05(-) did not contain DTPA. The excitation light intensity was set at 500 mV except when indicated otherwise.

AmR reacts with H_2O_2 forming the fluorescent dye xRed. The fluorescence intensity (proportional to the fluorescence signal) emitted in the AmR assay was calibrated by 0.1- μ M H_2O_2 titrations. At a gain setting of 1000, the amperometric raw signal of 1 μ A is converted to 1 V. Multiple H_2O_2 calibrations were performed at different states of the protocol to quantify the sensitivity of the AmR assay over time and experimental conditions (Kömlödi et al 2018). The fluorescence slope is calculated as the non-linear time derivative of the signal by DatLab 7.4.

2.6. Background fluorescence slope at air saturation

In contrast to an instrumental background effect, the chemical background fluorescence slope of the AmR assay increased over time in DPBS and KCl-medium at constant normoxic O_2 concentration near air saturation (~180 μ M; Figure 1a and b). The background fluorescence slope showed deviations from linearity above ~5-6 μ A fluorescence intensity in DPBS and KCl-medium. This can be explained by (1) the decreasing concentration of available AmR, and (2) the accumulation of xRed (or Res) over the course of the experiment leading to allosteric inhibition of HRP (Piwonski et al 2012). In MiR05, however, a moderate and linear increase of the background fluorescence slope over time was observed likely due to the antioxidant properties of the medium (Figure 1c). The background fluorescence slope $J_{amp,BGr}$ [$nA \cdot s^{-1}$] was a hyperbolic function of fluorescence intensity I_{amp} in KCl-medium (Figure 1d) but a linear function of I_{amp} in MiR05 with slope b_{amp} and intercept a_{amp} (Figure 1e),

$$\text{MiR05:} \quad J_{amp,BGr} = b_{amp} \cdot I_{amp} + a_{amp} \quad \text{Eq.1}$$

b_{amp} and a_{amp} were determined for each Lot of MiR05-Kit.

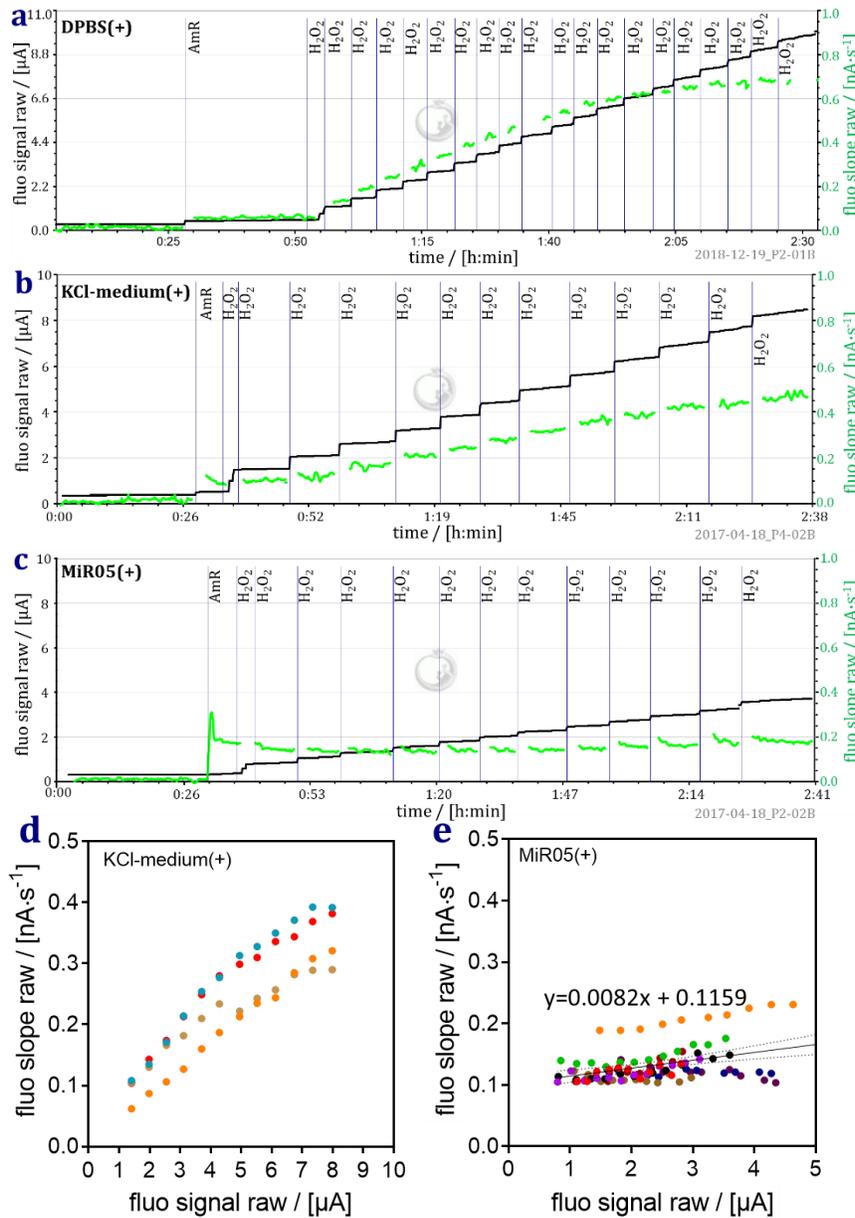

Figure 1. Background fluorescence slope in the Amplex UltraRed assay in different respiration media at constant O_2 concentration near air saturation ($\sim 170\text{-}180 \mu\text{M}$) in the presence of DTPA (+). (a) DPBS; (b) KCl-medium; (c) MiR05 (Lot#0915). Black plots: background fluorescence signal related to fluorescence intensity μA ; green plots: background fluorescence slope $\text{nA}\cdot\text{s}^{-1}$. Background fluorescence slope $\text{nA}\cdot\text{s}^{-1}$ as a function of fluorescence signal μA in (d) KCl-medium and (e) MiR05 (Lot#0915); each colour represents a separate experiment.

3. Results

Respiration (Figure 2a-c) and xRed fluorescence (Figure 2d-i) were measured in a sequence of normoxic-anoxic transitions. When rehydrated, freeze-dried yeast rapidly restored active metabolism (Crowe et al 1998). In DPBS and KCl-medium the apparent H_2O_2 flux increased with decreasing O_2 concentration resulting in a *hypoxic peak* of the fluorescence slope before it declined towards anoxia (Figure 2d and e). The hypoxic peak became increasingly prominent following each reoxygenation after anoxia. In MiR05, however, the hypoxic peak was not observed, but the apparent H_2O_2 flux declined continuously with decreasing O_2 concentration in a biphasic kinetic O_2 dependence (Figure 2f). How can these contradictory observations be explained? Is the hypoxic peak

related to acclimatization to O_2 availability and O_2 sensing of yeast in different buffers, or is it the result of a methodological artefact due to the interplay between respiration medium and the AmR assay?

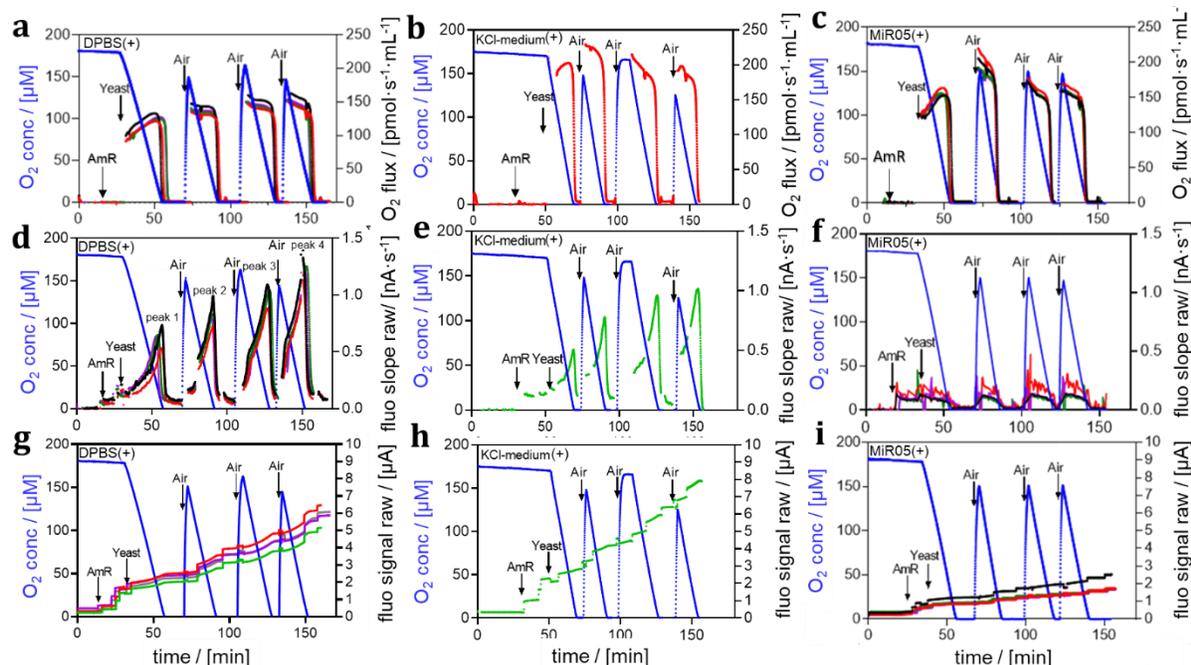

Figure 2. Amplex UltraRed assay and high-resolution respirometry in repeated normoxic-anoxic transitions in yeast measured in DPBS(+) (a, d, g), **KCl-medium(+)** (b, e, h), and **MiR05(+)** (c, f, i) with DTPA. Blue plots: O_2 concentration [μM] decreasing due to respiration; brief periods of anoxia were followed by reoxygenations. (a, b, c) Volume-specific O_2 flux [$\text{pmol}\cdot\text{s}^{-1}\cdot\text{mL}^{-1}$]; (d, e, f) non-calibrated fluorescence slope (raw) [$\text{nA}\cdot\text{s}^{-1}$]; (g, h, i) non-calibrated (raw) fluorescence signal (proportional to fluorescence intensity) [μA]. One representative trace (b, e, h) or technical repeats recorded in parallel in four different chambers (a, c, d, f, g, i). Experiments 2018-12-06_P3-02, 2018-12-06_P4-02, 2018-12-06_P1-01, 2018-12-06_P2-01, 2017-04-18_P7-02A.

3.1. Hypoxic H_2O_2 peak: fact or artefact?

The fluorescence signal increases over time owing to the accumulation of xRed originating from AmR due to (1) titrations of H_2O_2 during assay calibrations, (2) extracellular H_2O_2 production by yeast, and (3) artificial H_2O_2 -independent increase of background fluorescence (Figure 2g-i). To elucidate the origin of the hypoxic peak in DPBS and KCl-medium, we analysed the effect of fluorescence intensity (proportional to the fluorescence signal) on the apparent H_2O_2 flux. To differentiate between the effects of the O_2 regime and exposure time on H_2O_2 production by yeast and the effect of fluorescence intensity, we performed parallel experiments: the control group (C) with initial titration of AmR before adding yeast cells, and the experimental group (E) with delayed addition of AmR to yeast cells (Figure 3). Consistent with results shown in Figure 2d and e, the hypoxic peak was observed during the normoxic-anoxic transitions and

increased after each sequential reoxygenation in the controls (1C to 6C; Figure 3a and b). The hypoxic peak 4C was already highly pronounced. When AmR was added not at the start but only before transition 4E in the experimental group, however, the hypoxic peak 4E was comparable or even less pronounced than the hypoxic peak 1C in the control (Figure 3). Before transition 5E, titration of $0.8 \mu\text{M}$ H_2O_2 increased the fluorescence intensity which resulted in a hypoxic peak 5E of the same extent as 5C in the control. Importantly, O_2 flux did not differ in between the two parallel experimental regimes using yeast from the same batch (Figure 3a and c). These results suggest that the hypoxic peak observed in DPBS at low O_2 concentration was related to artificial background fluorescence intensity, excluding a redox response of yeast cells as an acclimatization to the O_2 regime.

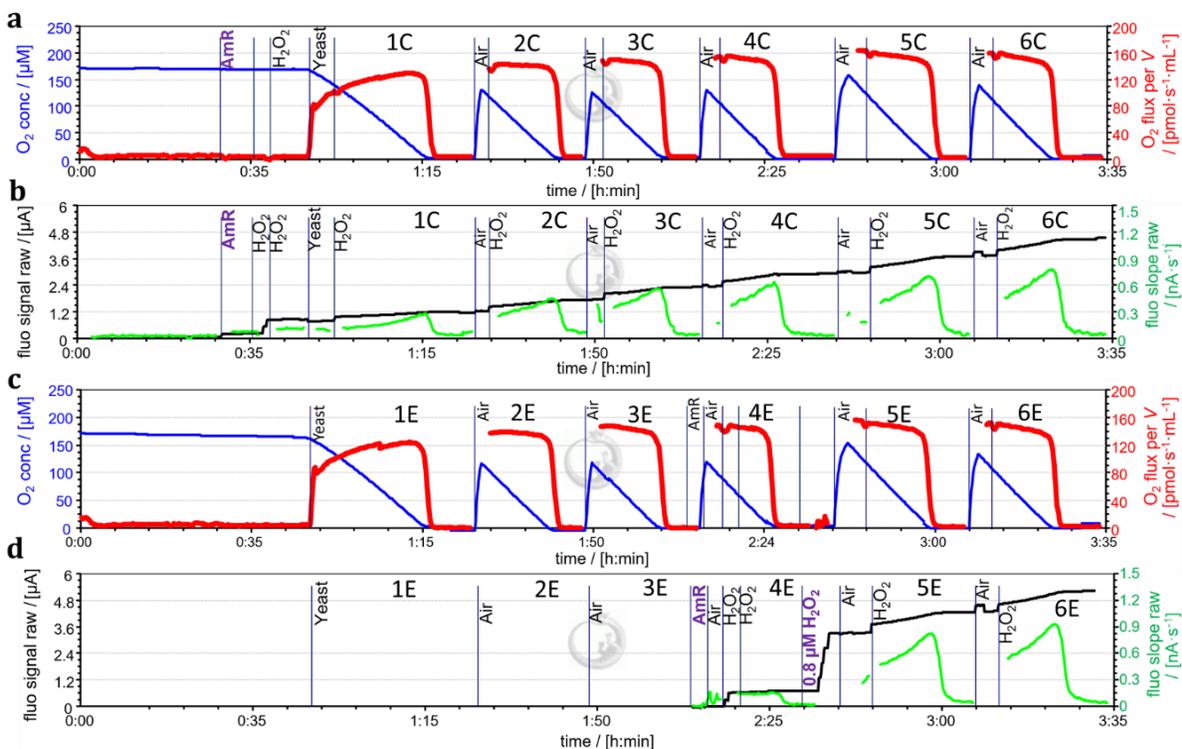

Figure 3. Effect of accumulating concentrations of xRed on the hypoxic peak of the fluorescence slopes in repeated normoxic-anoxic transitions in yeast incubated in DPBS(+) containing DTPA. Blue plots: O_2 concentration [μM] decreasing due to respiration; brief periods of anoxia were followed by reoxygenation. Red plots: volume-specific O_2 flux [$\mu\text{mol}\cdot\text{s}^{-1}\cdot\text{mL}^{-1}$]; black plots: non-calibrated fluorescence signal (proportional to fluorescence intensity) [μA]; green plots: non-calibrated (raw) fluorescence slope [$\text{nA}\cdot\text{s}^{-1}$]. 1C to 6C and 1E to 6E: normoxic-anoxic transitions. **(a, b)** Control: AmR titrated before addition of yeast; **(c, d)** Experimental group: AmR titrated immediately before 4E. The fluorescence intensity was increased by titration of $0.8 \mu\text{M}$ H_2O_2 before 5E. Experiment 2018-12-19 P8-02.

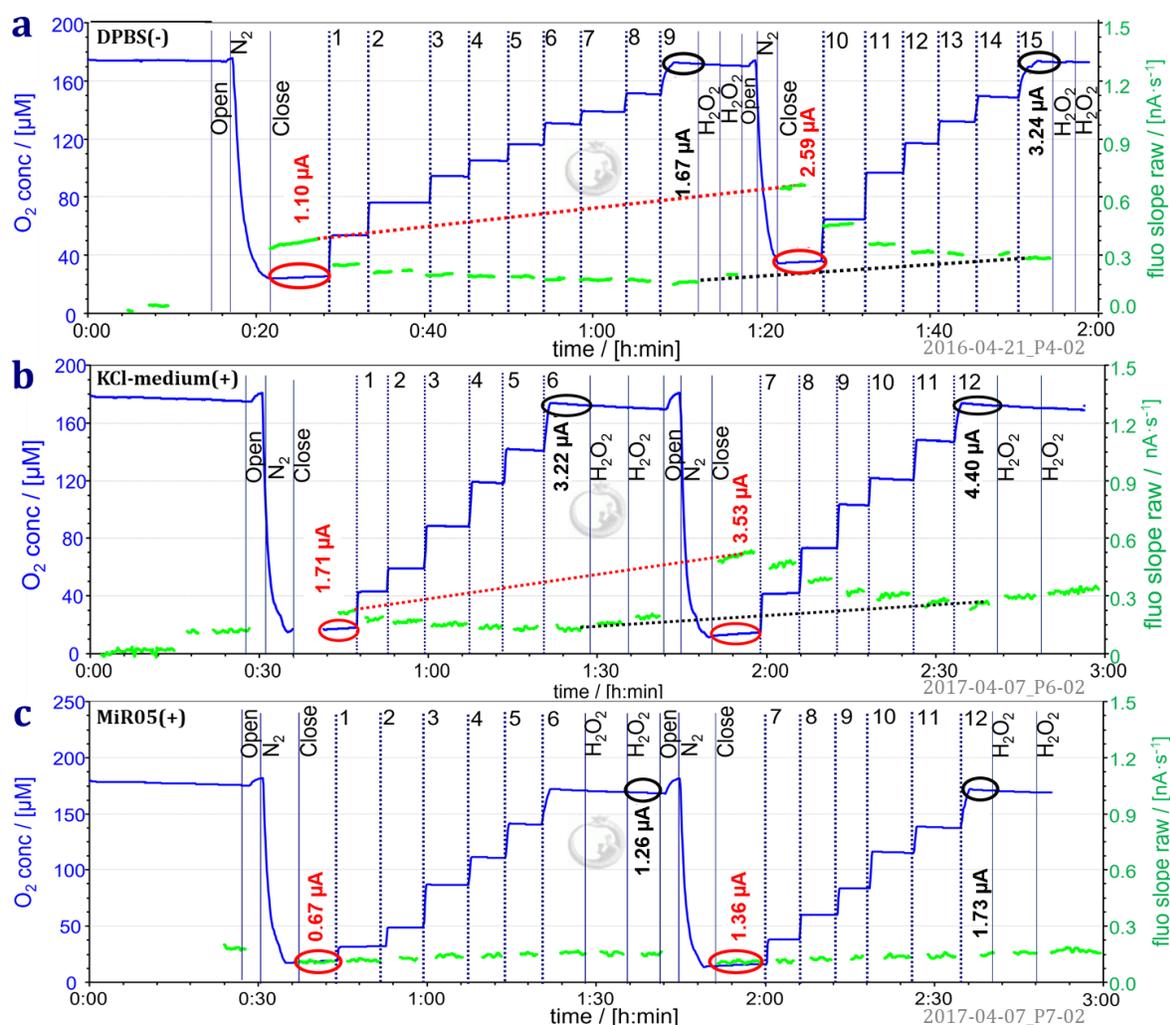

Figure 4. Oxygen dependence of the background fluorescence slope in the Amplex UltraRed assay. (a) DPBS(-); (b) KCl-medium(+); (c) MiR05(+). Blue plots: O_2 concentration [μM] was decreased with N_2 followed by increase of the O_2 concentration in several steps (1-15 and 1-12). Green plots: background fluorescence slope (raw) [$\text{nA}\cdot\text{s}^{-1}$]. The background fluorescence intensity (raw) [μA] is shown at low O_2 concentration (values shown in red) and at high O_2 concentration (values shown in black). Dotted lines: pronounced increase of the apparent H_2O_2 flux at low O_2 concentration as a function of the fluorescence intensity [μA] (values shown in red); less pronounced increase of the apparent H_2O_2 flux at high O_2 concentration as a function of fluorescence intensity (values shown in black).

3.2. Background fluorescence slope as a function of O_2 concentration

The background fluorescence slope is a result of artificial formation of Res (or xRed) independent of the biological sample, which depends on the respiration medium and excitation light intensity (Krumshnabel et al 2015; Zhao et al 2012). We investigated the background fluorescence slope in the AmR assay at different O_2 concentrations in DPBS, KCl-medium and MiR05 decreasing the O_2 level by N_2 gas injection followed by stepwise

elevation of O_2 concentration up to air-saturation ($\sim 180 \mu\text{M}$; [Figure 4](#)). In DPBS and KCl-medium (1) the fluorescence slope was high at low O_2 concentration and decreased with increasing O_2 concentration, (2) the fluorescence slope increased over time at the same O_2 concentration, and (3) the increase of fluorescence intensity over time was more pronounced at low O_2 concentration than at high O_2 concentration (fluorescence signals shown by red and black values [μA], respectively, in [Figure 4a and b](#)). In MiR05, however, the background fluorescence slope (1) increased only slightly from low to high O_2 concentrations, (2) did not change over time at the same O_2 concentration, and (3) the final fluorescence intensity of $1.7 \mu\text{A}$ in MiR05 was lower compared to DPBS and KCl-medium ([Figure 4c](#)).

We further investigated the fluorescence slope in the AmR assay with DPBS and MiR05 in the absence and presence of yeast ([Figure 5](#)). In DPBS a hyperbolic relationship was observed between the background fluorescence slope and fluorescence intensity ([Figure 5a](#)). The same pattern was observed at excitation light intensities of 500 mV ([Figure 5a](#)) and 250 mV ([Figure 5g](#)). The background fluorescence slope increased with decreasing O_2 concentration ([Figure 5b](#)). Moreover, the hypoxic peaks observed with yeast cells in the reoxygenation cycles matched the pattern of the background fluorescence slope in DPBS. The hypoxic peaks in the presence of yeast occurred at O_2 concentrations in the range of $5 \mu\text{M}$ to $10 \mu\text{M}$ which were below the O_2 levels obtained in the chemical background measurements. This shows that the hypoxic peaks were indistinguishable from the background fluorescence slope in DPBS.

In MiR05 the background fluorescence slope was low compared to DPBS ([Figure 5c and d](#)). An increase of the background fluorescence slope with fluorescence intensity becomes apparent at enlarged scales ([Figure 5e](#)). The O_2 concentration exerted only a subtle effect on the background fluorescence slope (zoom in [Figure 5f](#)). The fluorescence slope measured in the presence of yeast at high O_2 concentrations was higher than the background fluorescence slope and it decreased at low O_2 levels overlapping with the background fluorescence slope. The background-corrected fluorescence slopes, therefore, indicate a decline of extracellular H_2O_2 flux from high to low O_2 concentration.

3.3. Background correction

In DPBS, the high background fluorescence slope overlapping with the experimental fluorescence slope in the presence of yeast made it impossible to apply a meaningful background correction.

For experiments in MiR05, we calculated the background flux $J_{\text{amp,BG}}$ applying the following step-wise background corrections.

1. Linear dependence on fluorescence intensity I_{amp} [μA] measured at the reference O_2 concentration $[O_2]_r$ which was close to air saturation ([Figure 1e](#), [Table 2](#)).
2. Linear dependence on O_2 concentration ([Figure 5f](#)) described by the oxygen correction factor F_{O_2} , $[O_2]_e$ is the experimental O_2 concentration at a given respiratory state,

$$F_{O_2} = (0.0002 \cdot [O_2]_e + 0.067) / (0.0002 \cdot [O_2]_r + 0.067) \quad \text{Eq.2}$$

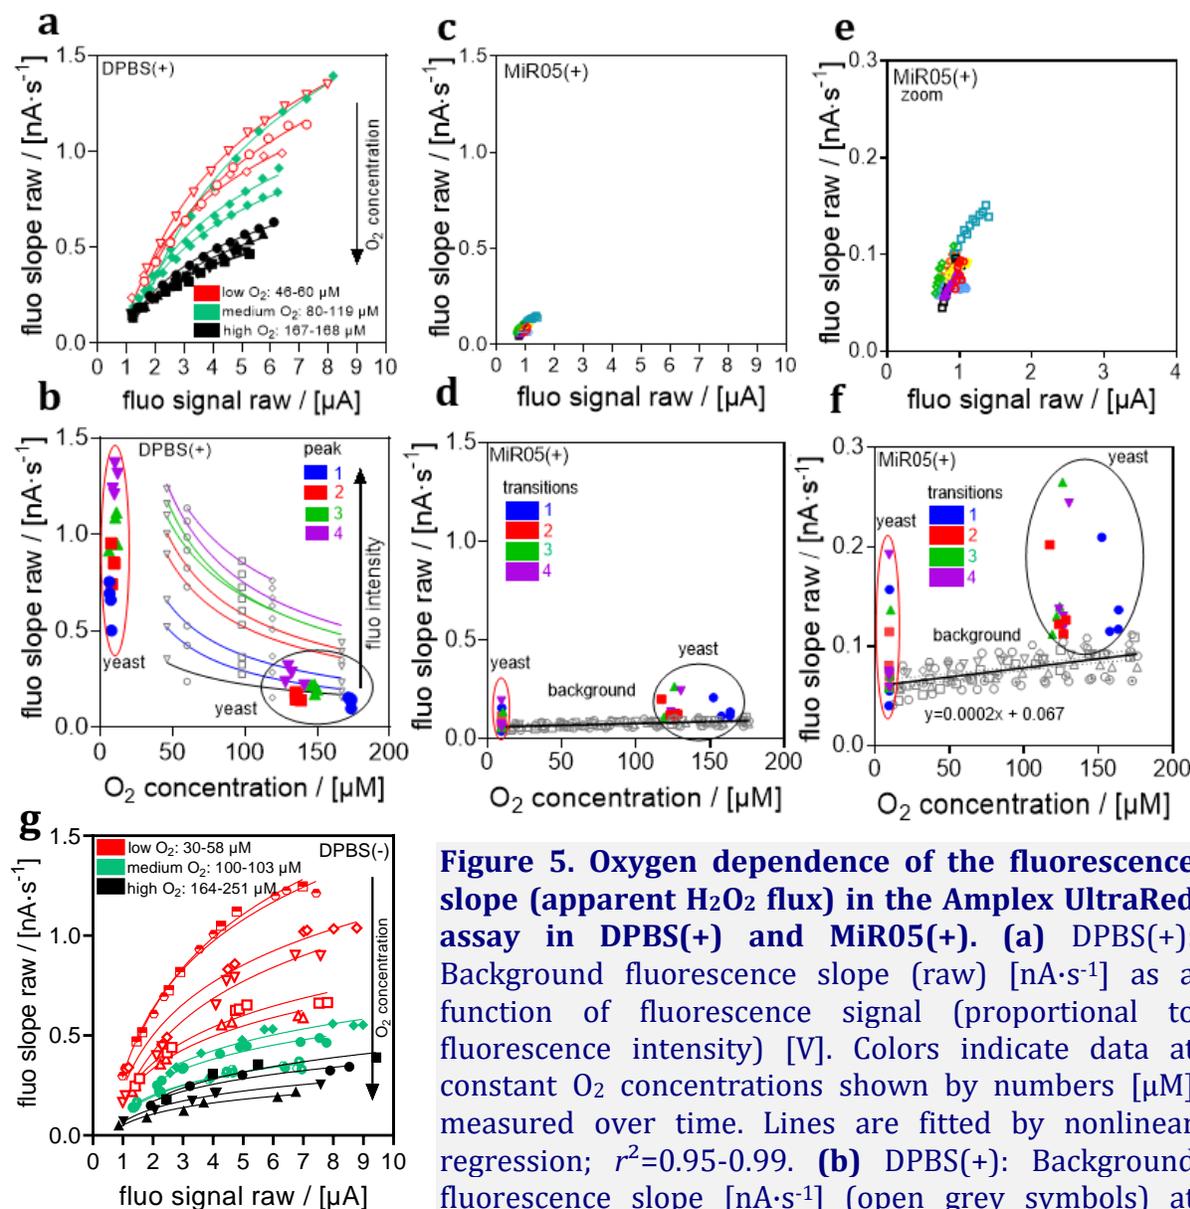

Figure 5. Oxygen dependence of the fluorescence slope (apparent H₂O₂ flux) in the Amplex UltraRed assay in DPBS(+) and MiR05(+). **(a)** DPBS(+): Background fluorescence slope (raw) [nA·s⁻¹] as a function of fluorescence signal (proportional to fluorescence intensity) [V]. Colors indicate data at constant O₂ concentrations shown by numbers [μM] measured over time. Lines are fitted by nonlinear regression; $r^2=0.95-0.99$. **(b)** DPBS(+): Background fluorescence slope [nA·s⁻¹] (open grey symbols) at constant O₂ concentrations (from panel a) as a function of O₂ concentration [μM] and fluorescence slope [nA·s⁻¹] at the peak in the presence of yeast at low (red circle) and high (black circle) O₂ concentrations in the reoxygenation cycles (closed symbols). Colors distinguish peaks (1-4) in the first to fourth transitions. Identical symbols indicate data from an individual assay (technical repeats; $n=4$). For representative trace, see Figure 2d. Each line is fitted by nonlinear regression through data points at constant fluorescence signal; $r^2=0.96-0.99$. Colors of lines refer to the similar fluorescence signal as measured in the transition peaks. **(c)** MiR05(+): Background fluorescence slope (raw) [nA·s⁻¹] as a function of fluorescence signal [V] measured at different O₂ concentrations [μM] as shown in Figure 2f. Each colour represents a separate experiment. **(d)** MiR05(+): Background fluorescence slope [nA·s⁻¹] (open grey symbols) as a function of O₂ concentration [μM] and non-calibrated fluorescence slope measured at low (red circle) and high O₂ (black

circle) concentrations in the presence of yeast in the first to fourth (1-4) transitions distinguished by colors. Line is fitted by linear regression, equation of the plot; $r^2=0.80$. Identical symbols indicate data from an individual assay (technical repeats; $n=4$). **(e)** Zoom into panel **c**. **(f)** Zoom into panel **d**. **(g)** DPBS(-) without DTPA: Oxygen dependence of the background fluorescence slope at excitation light intensity 250 mV; $r^2=0.95-0.99$. Compare with panel **a** at excitation light intensity 500 mV and DPBS(+).

3. Oxygen-adjusted background fluorescence slope $J_{amp,BG}$ [$\text{nA}\cdot\text{s}^{-1}$],

$$J_{amp,BG} = J_{amp,BGr} \cdot F_{O_2} \quad \text{Eq.3}$$

4. Background-corrected experimental fluorescence slope $J_{amp,corr}$ [$\text{nA}\cdot\text{s}^{-1}$] based on the experimental fluorescence slope in the presence of sample J_{amp} [$\text{nA}\cdot\text{s}^{-1}$] at $[O_2]_e$,

$$J_{amp,corr} = J_{amp} - J_{amp,BG} \quad \text{Eq.4}$$

5. Calibration for H_2O_2 -sensitivity [$\mu\text{A}\cdot\mu\text{M}^{-1}$] determined from H_2O_2 calibrations (Kömlödi et al 2018) to obtain extracellular H_2O_2 flux $J_{H_2O_2}$ [$\text{pmol}\cdot\text{s}^{-1}\cdot\text{mL}^{-1}$],

$$J_{H_2O_2} = J_{amp,corr} / \text{sensitivity} \quad \text{Eq.5}$$

Table 2. Background parameters for different Lots of MiR05-Kit. Assays with DTPA. Slope b_{amp} and intercept a_{amp} (Eq.1; Materials and methods).

20 01923	-0.0348	0.1248

3.4. O_2 kinetics of H_2O_2 flux and O_2 flux

O_2 consumption and xRed fluorescence slope (apparent H_2O_2 flux) were measured simultaneously in repeated normoxic-anoxic transitions in yeast cells in MiR05 and DPBS (Figure 6 and 7). During the first transition the cells acclimatized to experimental conditions immediately after rehydration. At normoxic O_2 concentration yeast respiration stabilized during the following reoxygenation cycles (Figure 2a, 2c and 3). Therefore, we analysed the second transitions (Figure 6a and b).

Respiration was a complex function of O_2 concentration in the high O_2 regime including factors of time and non-mitochondrial O_2 consumption (Gnaiger et al 1995). A zoom into the low O_2 range reveals first-order hyperbolic kinetics (Figure 6c). The maximum kinetic O_2 flux (J_{max}) varied as a function of respiration media and the number of normoxic-anoxic transitions (experimental exposure time). J_{max} was calculated as a parameter of the hyperbolic fit indicating O_2 flux at high, non-limiting O_2 concentrations (see Materials and methods). The p_{50} was about four times higher than the p_{50} of isolated mitochondria and small mammalian cells, indicating the effect of intracellular diffusion gradients in the yeast cells (Gnaiger 2003; Scandurra, Gnaiger 2010). c_{50} (p_{50}) varied as a function of J_{max} (Figure 6d) consistent with the concept of kinetic electron trapping by

cytochrome *c* oxidase (Verkhovsky et al 1996; Gnaiger 2001). This indicates that the incubation medium did not exert any specific effect on respiratory O_2 kinetics. In contrast, there was a dramatic difference in the dependence of apparent H_2O_2 flux on O_2 concentration in different media. In DPBS a sharp hypoxic peak of J_{amp} was observed at low O_2 concentration (uncorrected; Figure 6b). In MiR05, however, background-corrected $J_{H_2O_2}$ remained low and was a linear function of O_2 concentration in the hyperoxic to hypoxic range (Figure 6a). A higher resolution of H_2O_2 flux was obtained in a separate batch of yeast which showed increased respiration and H_2O_2 flux near air saturation (Figure 7). The H_2O_2 flux was a biphasic function of O_2 concentration, with a linear decline in the normoxic to hypoxic range and a steep decline of H_2O_2 flux in the microoxic range when respiration was limited by O_2 concentration.

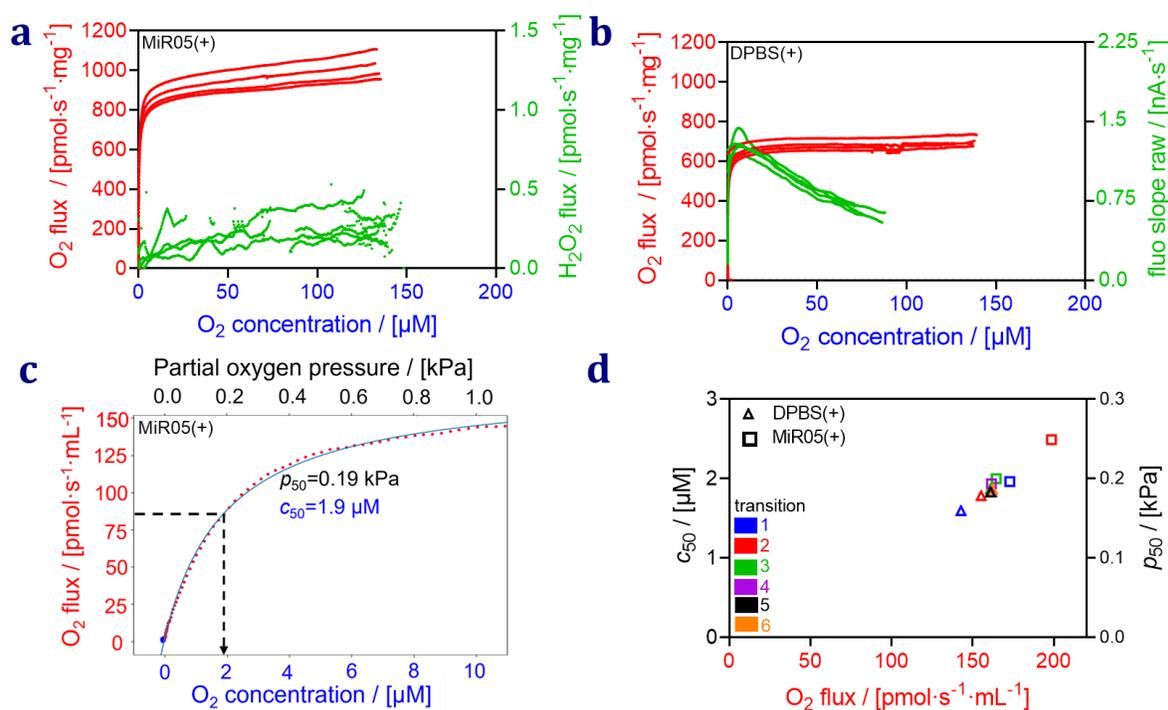

Figure 6. O_2 flux and H_2O_2 flux as a function of O_2 concentration in yeast cells (37 °C). (a) MiR05(+); (b) DPBS(+); second normoxic-anoxic transitions in the ROUTINE state in four technical repeats. Data are from Figure 2d and f. Red plots: mass-specific O_2 flux [pmol·s⁻¹·mg⁻¹]; (a) green plots: H_2O_2 flux is shown after H_2O_2 calibration performed at ~150 μM O_2 ; (b) fluorescence slope J_{amp} ; (c) O_2 kinetic plot of respiration with zoom into the low O_2 concentration range. Volume-specific O_2 flux J_{V,O_2} [pmol·s⁻¹·mL⁻¹] as a function of O_2 concentration and partial oxygen pressure p_{O_2} [kPa] in MiR05. Dots show individual data points measured at 2-s time intervals. Blue line: hyperbolic fit. Experiment 2018-12-06_P4-02A from Figure 2c, second transition. (d) c_{50} [μM] and p_{50} [kPa] as a function of maximum volume-specific O_2 flux J_{max} at identical yeast concentrations in MiR05 and DPBS for the first to fourth transitions. Colors distinguish peaks (1-6) in the first to fourth transitions.

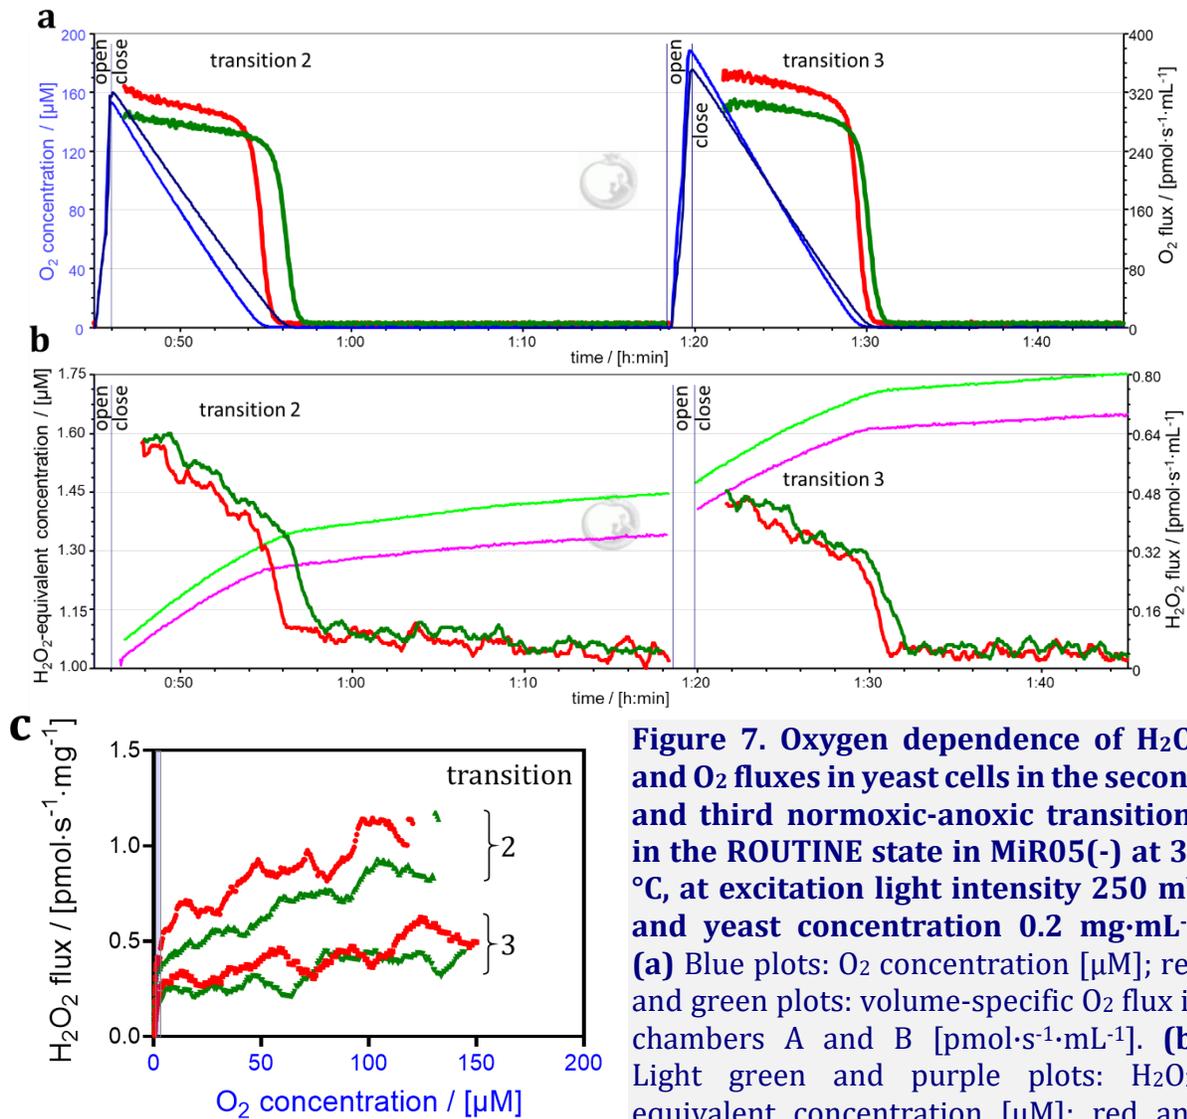

Figure 7. Oxygen dependence of H₂O₂ and O₂ fluxes in yeast cells in the second and third normoxic-anoxic transitions in the ROUTINE state in MiR05(-) at 37 °C, at excitation light intensity 250 mV and yeast concentration 0.2 mg·mL⁻¹. (a) Blue plots: O₂ concentration [μM]; red and green plots: volume-specific O₂ flux in chambers A and B [pmol·s⁻¹·mL⁻¹]. (b) Light green and purple plots: H₂O₂-equivalent concentration [μM]; red and green plots: volume-specific H₂O₂ flux [pmol·s⁻¹·mL⁻¹] in chambers A and B. (c) Mass-specific H₂O₂ flux [pmol·s⁻¹·mg⁻¹] from panel b corrected for background fluorescence slope. Shaded area indicates the low-oxygen range when respiration declined as a hyperbolic function of oxygen (Figure 6). Experiment 2016-03-03_P12-02.

4. Discussion

Besides H₂O₂-independent formation of xRed (or Res), several potential methodological artefacts are discussed in the literature related to the metabolites or enzyme activities in the biological sample. (1) Res can undergo a one-electron reduction to form a semiquinoneimine-type radical which regenerates AmR and superoxide anion by NADPH-cytochrome P450 reductase in liver microsomes (Dutton et al 1989). (2) Complex I can initiate cycling of oxidized and reduced Res in the presence of NADH and other reductants (Grivennikova et al 2018). (3) HRP can catalyze the oxidation of Res in

the presence of peroxyxynitrite, and peroxyxynitrite-derived radicals can oxidize AmR to Res (Debski et al 2016). (4) In liver and kidney, AmR can be converted to Res/xRed by mt-carboxylesterases mtCES which can be prevented using mtCES inhibitors such as phenylmethyl sulfonyl fluoride (Miwa et al 2015). These side-effects can be practically excluded in our experiments with living yeast. We added SOD to all AmR assays to not only convert superoxide to H₂O₂ and O₂ but to minimize formation of Res (or xRed) in a photosensitized reaction with NADH and reduced glutathione (Votyakova, Reynold 2004; Zhao et al 2011, 2012).

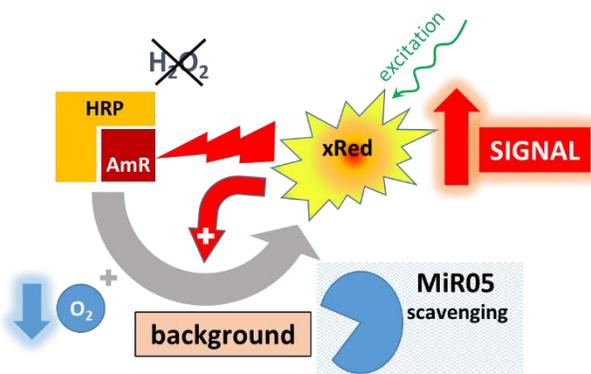

Figure 8. UltraxRed (xRed) formation in H₂O₂-independent reactions in the absence of biological sample. xRed is formed in the absence of H₂O₂ in the AmR-HRP reaction contributing to the background fluorescence slope. Excitation light can initiate xRed generation which induces further xRed formation via photooxidation of AmR in a self-amplification process. These phenomena and the decrease of O₂

concentration result in the increase of the background fluorescence signal which is scavenged by the antioxidants in MiR05 thus preventing the hypoxic peak.

In the present study we investigated the O₂ dependence of extracellular H₂O₂ flux in yeast. In DPBS and KCl-medium, a hypoxic peak was observed at low O₂ concentration, which increased with the sequential number of reoxygenations and normoxic-anoxic transitions. Theoretically this increase of the fluorescence slope might indicate H₂O₂ formation triggered by reductive stress at low O₂ concentrations and hypoxic preconditioning (Hernansanz-Agustín et al 2014; Smith et al 2017). However, the hypoxic peak could be explained entirely as background fluorescence slope. The hypoxic peak is a methodological artefact caused by autooxidation of AmR at increasing fluorescence intensity and under hypoxia in the range of 5 μM to 10 μM O₂ corresponding to 2.5 % to 5 % air saturation (Figure 8).

MiR05 is optimized for assessment of respiration during prolonged incubation times to preserve mitochondrial function (Gnaiger et al 2000). The sensitivity of the AmR assay is more stable in MiR05 than in DPBS, KCl-medium, and buffer Z in experiments up to 2 h (Komlódi et al 2018). This was confirmed in the present background experiments at air saturation (Figure 1). Importantly, MiR05 prevented the artefact of the hypoxic peak (Figure 4 and 5). This might be explained by the high antioxidant capacity of MiR05 (Figure 8; Gnaiger et al 2000). However, preliminary results suggest that the artefact of the hypoxic peak does neither occur in 50 mM phosphate buffer, at higher yeast concentration (1.5 mg/mL), low excitation light intensity (100 mV), and lower temperature (28 °C; Supplement Figure S1). In agreement with Li Puma et al (2020), a linear relationship was observed between O₂ concentration and background fluorescence slope in the AmR assay measured in MiR05. This provides the basis for correction for

background fluorescence slope and evaluation of the O_2 dependence of H_2O_2 flux. Importantly, the H_2O_2 flux of yeast in MiR05 was linearly dependent on O_2 concentration; H_2O_2 flux did not increase at low O_2 concentration even after multiple normoxic-anoxic transitions (Figure 2 and 7). This observation is in line with studies by Boveris and Chance (1973), Duong et al (2020), Li Puma et al (2020), Robb et al (2018), Stepanova et al (2017, 2018a, 2018b, 2020), and Szibor et al (2020) showing a linear increase of H_2O_2 production with O_2 concentration. These results, however, contrast with the concept of reductive stress and elevated hypoxic H_2O_2 generation (Chandel et al 1998; Guzy et al 2007; Hernansanz-Augustin et al 2014; Waypa et al 2001). The viability of CuZnSOD null mutants of *S. cerevisiae* is compromised at normoxia but not at low aeration levels (Longo et al 1996), consistent with decreased ROS production under hypoxia corresponding to intracellular oxygen pressures of mammalian cells in tissues.

Conclusions

In studies of H_2O_2 flux as a function of O_2 concentration using the AmR assay, the respiration medium MiR05 offers advantages compared with DPBS and KCl-medium. An apparent maximum of H_2O_2 production under hypoxia was explained as chemical background-related artefact in DPBS and KCl-medium. The background fluorescence slope and its O_2 dependence are minimized in MiR05, allowing for accurate background correction. Under these conditions, extracellular H_2O_2 flux of living yeast showed a biphasic oxygen dependence. H_2O_2 flux decreased abruptly towards anoxia when respiration showed a hyperbolic dependence on O_2 concentration. Above this critical O_2 concentration, H_2O_2 flux increased linearly from hypoxia to hyperoxia at constant respiration.

Abbreviations

a_{amp}	intercept	$J_{amp,corr}$	background-corrected experimental fluorescence slope
AmR	Amplex UltraRed	$J_{H_2O_2}$	hydrogen peroxide flux
b_{amp}	slope	J_{max}	maximum volume-specific oxygen flux
DPBS	Dulbecco's Phosphate Buffered Saline	J_{V,O_2}	volume-specific oxygen flux
DCFH	2',7'-dichlorofluorescein	I_{amp}	fluorescence intensity
DHE	dihydroethidine	KCl	potassium-chloride
DTPA	diethylenetriamin-N,N,N',N'',N'''-pentaacetic acid	mtCES	mt-carboxylesterases
c_{50}	oxygen concentration at which respiratory flux is 50 % of J_{max}	$[O_2]_e$	experimental oxygen concentration
ETS	electron transfer system	$[O_2]_r$	reference oxygen concentration
F_{O_2}	oxygen correction factor	p	oxygen partial pressure [kPa]
HRP	horseradish peroxidase	p_{50}	oxygen partial pressure at which respiratory flux is 50 % of J_{max}
H_2O_2	hydrogen peroxide	Res	resorufin
J_{amp}	experimental fluorescence slope	ROS	reactive oxygen species
$J_{amp,BG}$	oxygen-adjusted background fluorescence slope	SOD	superoxide dismutase
$J_{amp,BGr}$	raw background fluorescence slope	xRed	UltroXRed

Acknowledgements

We thank Manuela Passrigger, Marco Di Marcello for excellent technical support in buffer preparation, and maintenance of the O2ks, Marco Di Marcello for analysis of the p_{50} data, and Carolina Doerrier for valuable comments on the manuscript. This work was partially funded by project NextGen-O2k which has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement N° 859770. Ondrej Sobotka's secondments were founded by PROGRES Q40/02.

Supplement

Respiration of freeze-dried yeast suspended in 50 mM Na-phosphate buffer was stimulated by extracellular glucose (Figure S1a). Subsequently, respiration further doubled upon stimulation by ethanol and uncoupler titrations (not shown). These additions exerted a minor effect on extracellular H₂O₂ production, which was a linear function of environmental oxygen concentration in the hypoxic to hyperoxic range (Figure S1b and c). The biphasic oxygen dependence of H₂O₂ flux obtained in Na-phosphate buffer was comparable with results in MiR05 (Figure 7).

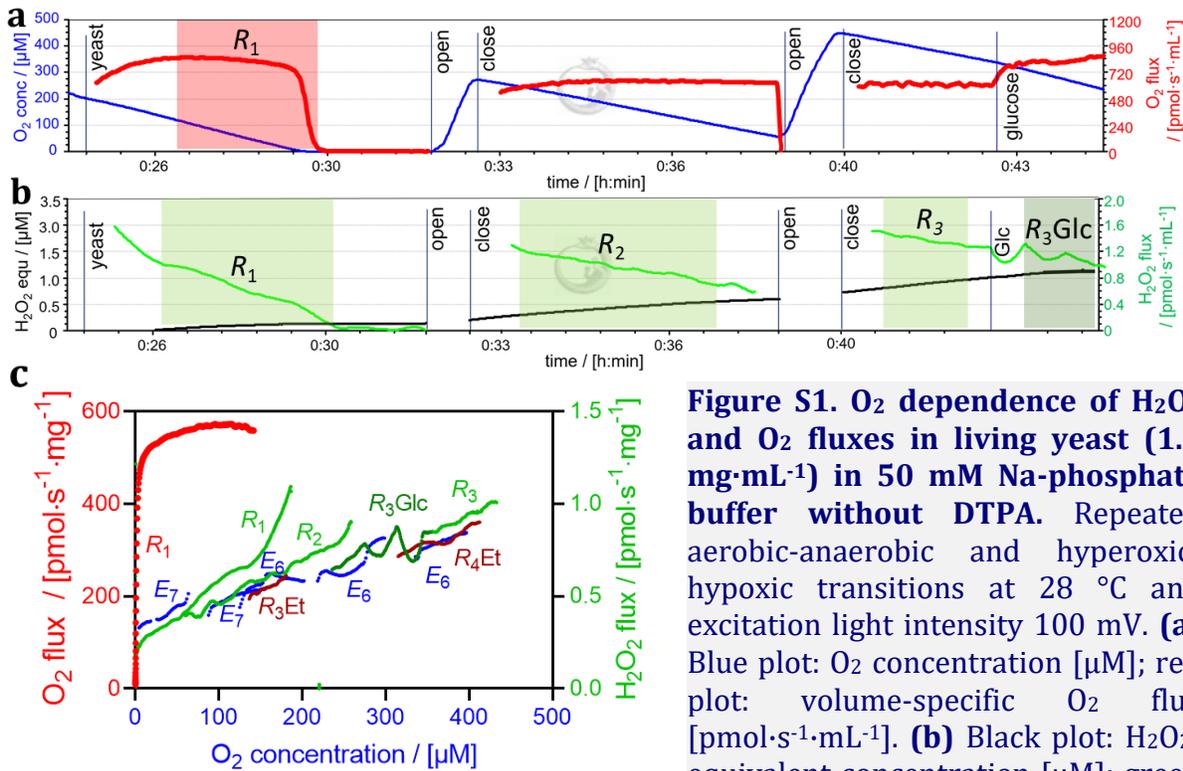

Figure S1. O₂ dependence of H₂O₂ and O₂ fluxes in living yeast (1.5 mg·mL⁻¹) in 50 mM Na-phosphate buffer without DTPA. Repeated aerobic-anaerobic and hyperoxic-hypoxic transitions at 28 °C and excitation light intensity 100 mV. **(a)** Blue plot: O₂ concentration [μM]; red plot: volume-specific O₂ flux [pmol·s⁻¹·mL⁻¹]. **(b)** Black plot: H₂O₂-equivalent concentration [μM]; green plot: volume-specific H₂O₂ flux [pmol·s⁻¹·mL⁻¹].

(c) Mass-specific O₂ flux [pmol·s⁻¹·mg⁻¹] from panel a in the first reoxygenation cycle (R₁), and biphasic oxygen dependence of mass-specific H₂O₂ flux [pmol·s⁻¹·mg⁻¹] from panel b in the first, second and third reoxygenation cycles in the ROUTINE state (R₁, R₂, R₃), after glucose (20 mM) addition in the third reoxygenation cycle (R₃Glc), after ethanol (20 μL/mL) addition in the third (R₃Et) and fourth (R₄Et) reoxygenation, after uncoupler titration (2.5 to 30 μM carbonyl cyanide p-trifluoromethoxyphenyl hydrazone FCCP) in the sixth (E₆) and seventh reoxygenation (E₇). Experiment 2012-03-20_EF-02A.
